Abstract

In a global economy, fair and universal management of worldwide markets with a guarantee of sustainability of life on this planet is a key element. In this work, a universal measure of emissions to be applied at the international level is proposed, based on a modification of the Greenhouse Gas Intensity (GHG-INT) measure. It is hoped that the generality and low administrative cost of this measure, which we call the Modified Greenhouse Gas Intensity measure (MGHG-INT), will eliminate any need to classify nations, and provide a uniform approach to penalizing emissions. The core of the MGHG-INT is what we call the Modified Gross Domestic Product (MGDP), based on the Inequality-adjusted Human Development Index (IHDI). The MGDP enables us to normalize the status of all nations on a common scale, making it possible for us to propose universal measures, such as MGHG-INT. We also propose a carbon border tax, either as a direct tax or a tax adjustment, applicable at national borders, based on MGHG-INT and MGDP. This carbon tax is supported by a proposed global Emissions Trading System (ETS) applied at the international level. It is assumed that each country will implement its own equivalent carbon tax system to preserve the competitiveness of the marketplace; however, consideration of this aspect of our concept is beyond the scope of our work here. The proposed carbon tax is analyzed in a short-term scenario with interesting outcomes, such as the simultaneous lowering of emissions levels and the maintenance of reasonable growth in MGDP. The proposed carbon tax and ETS can also be implemented at the national level in a country, in provincial or corporate slices. In addition to annual GHG emissions, cumulative GHG emissions over a decade are considered for the big players in the world economy with almost the same results.

Key words: Global Warming, Greenhouse Gases, C O2 Emissions, Global Economy, Emission Efficiency.

1 Introduction

The Kyoto protocol, one of most successful global initiatives ever proposed, is based on the hypothesis that a nation's economy is independent of the economies of other nations. This hypothesis is a reflection of the macro-canonical approach of the protocol's designers, and led to a commitment to reduce emissions to 5.2% percent below 1990 levels between 2008 and 2012. However, in our highly interconnected global economy and with new economic heavy-weights now on the scene, a more pragmatic approach is required to achieve a strategic goal such as the reduction of global GHG emissions [16, 4, 15, 25, 34, 33, 37, 35, 36, 38, 40, 41, 47, 46].

It is worth noting that, despite a general tendency to blame CO_2 emissions on non-green activities, any human footprint in nature, such as energy consumption (heat generation), Greenhouse Gas (GHG) emissions, and water usage, could be considered as a non-green act. We can even argue that wind energy is greener than solar energy, because it extracts energy from the earth's atmospheric system and helps stabilize it, while the latter absorbs solar energy from outside the atmospheric system and confines it in the earth system. That said, CO_2 and GHG emissions still have the greatest impact on the environment and on the earth's atmospheric stability, and are the focus of this work.

Although several emissions indicators have been devised, such as greenhouse gas intensity (GHG-INT) and emissions per capita, there is no global agreement on any of them, as such measures can be very well received in one country and highly unpopular in others.

In this work, a general indicator and measure of emissions is introduced to resolve the issues of world-level dissolution and lack of agreement. This indicator, which we call the Modified GHG Intensity (MGHG-INT) measure, not only takes into account the global influence of a nation in terms of its productivity (external "activity"), but also attempts to include its heretofore ignored "activity" to arrive at a universal emissions measure which can be used to evaluate a nation's contribution to the unsustainability of the planet, and also to react to it.

Despite the commonly held belief that World Trade Organization (WTO) regulations prevent the imposition of a carbon border tax, several groups are poring over World Trade Agreement (WTA) articles to find a way to implement such a tax [39, 30, 31, 26, 43, 6]. A border tax is a direct tax on imported goods, while a border tax adjustment (BTA) involves the imposition of a domestically imposed excise tax on “like” imported goods that are not sustainably produced [50]. The United States and European countries in particular are working toward a border tax adjustment, which may also cover carbon leakage [43]. There are many possible options in the WTO regulations that can be used to impose a border tax or BTA to control and reduce global GHG emissions. For example, Article II: 2(a) of the General Agreement on Tariffs and Trade (GATT) allows members of the WTO to place a border tax on the importation of any good, equivalent to an internal tax on a “like”, or similar, good, and Article III: 2 of the GATT states that a BTA cannot be applied in excess of that applied directly or indirectly on a similar domestic good. If we read the wording of these articles in reverse, we find that any carbon border tax is possible, as long as an equivalent internal tax is implemented. The equivalent internal tax mechanisms are beyond the scope of this work, as we focus here solely on the carbon border tax. The most important aspect of border taxes is trade neutrality [39, 30]. Also, some work has been conducted on applying uniform carbon taxes and analyzing their impact on the carbon footprint and economy in different sectors [45]. However, those work does not consider the contribution of the country of origin to the global carbon footprint, but only the emissions related to the production of the good itself.

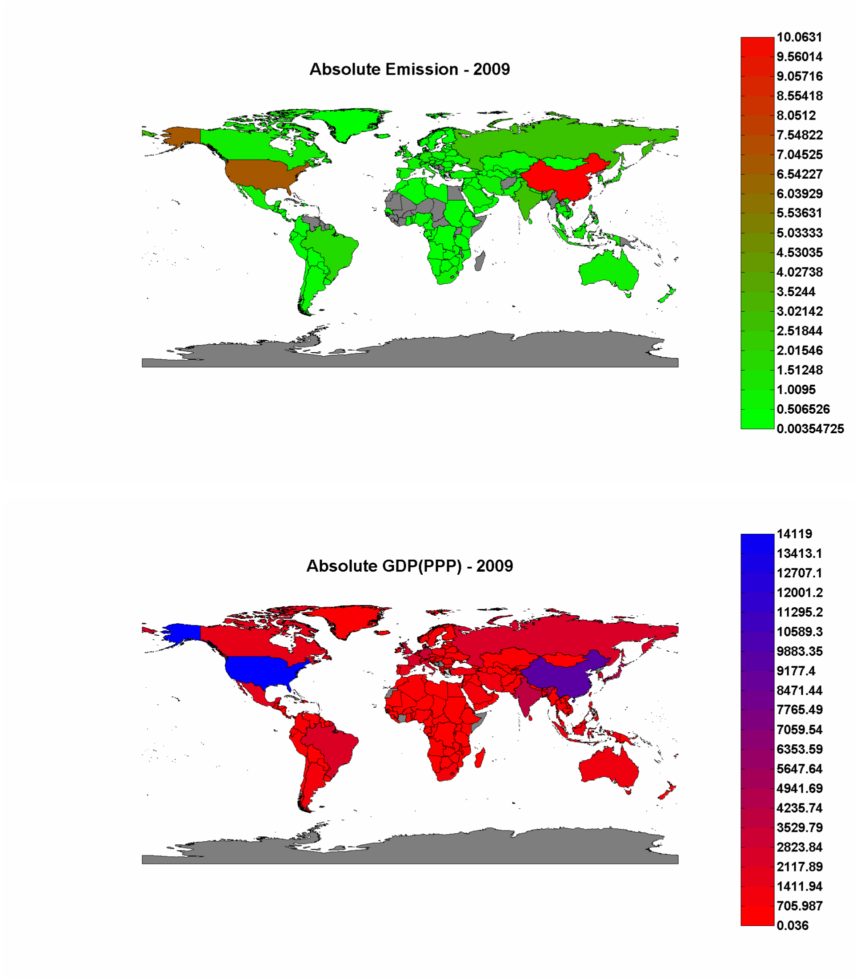
Usually, CO_2 emissions come from three sources: burning to produce energy and food, emitting in the concrete industry, and emitting as the result of land use. The proposed carbon tax manages the emissions related to energy and food production, while the proposed ETS, which provides a means for emissions trading to reduce carbon taxes, covers land-use emissions. The details of this tax are provided in the following sections. In brief, a carbon tax mechanism to be implemented at a country’s border as a border tax or a border tax adjustment is proposed, which consists of two terms:

$$\text{Carbon tax of origin} + \text{Transportation carbon tax}$$

Because of complexity of transportation mechanisms, this term has been separated from the carbon tax of origin. In this work, we just consider only the carbon tax of origin.

The paper is organized as follows. In section 2, the motivations for the new emissions indicator and measure is presented in greater detail. The definitions of MGDP and MGHG-INT are presented in section 3. The RED percentage is defined in section 4, and used to define the proposed carbon tax in section 5. A simulation of the impact of a carbon border tax on the world economy is presented in section 5.1. The proposed ETS is provided in section 5.2. Finally, our concluding remarks and future research prospects are presented and discussed in section 6. In section A of the appendix, common notations and definitions used in other sections are introduced. The issue of the accumulation of GHG emissions over a decade is discussed in section B of the appendix. Also, full-size tables of various variables and indicators are presented in section C, as supplementary material.

2 Motivations



(a)

(b)

Fig. 1. a) Global picture of GHG emissions (in gigatonnes of carbon dioxide equivalent (GtCO2e)) in 2009. b) Global distribution of GDP (PPP) in the same year (in billions of international dollars).

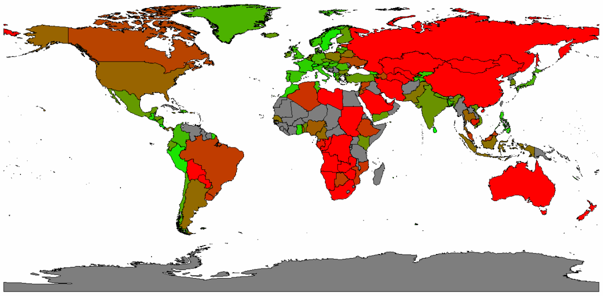

Fig. 3. What an ideal indicator of emissions should look like, and which the MGHG-INT, introduced in section 3, will provide.

Figure 1 shows the status of the world in terms of GDP and emissions in 2009. While there have been some fluctuations, the overall picture remains the same today, with the presence of two heavy-weights, the United States and China. One would think, therefore, that control and penalty measures designed to reduce the human footprint on nature will have the same distribution across the world. However, traditional measures, such as GHG Emission Intensity (GHG-INT) and GHG emissions per capita, penalize only one of the two major emitters, ignoring the other one (see Figure 2). The reason for this could be related to fundamental differences in the composition of these two countries. However, all countries evolve over time, and proposing a measure based on the current status of a country is not recommended, as it may prove ineffective (or even have an unintended effect) in the future. Our objective is to provide a measure which covers all emitters uniformly, despite their differences. This new measure, shown pictorially in Figure 3, should be stable over time, high-level, and easy to calculate. We call it the Modified GHG Intensity (MGHG-INT), as we think it should calculate performance with respect to "activity". The details of this proposed measure are provided in section 3 based on a modified gross domestic product, or MGDP.

Before proceeding to the definition of MGDP and MGHG-INT, we provide below a list of the global threats that support the urgent need for a new universal measure.

2.1 Threats: Global disagreement on emission reduction goals, measures, and procedures.

In a highly interconnected world economy, global goals and measures can result in advantages for exporting countries. This will force, and has forced, many developed countries to abandon such goals and measures, and adopt the strategy that best suits their needs. Canada, for example, changed its goal from meeting the Kyoto targets to the new goal of reducing emissions intensity in 2006 [14]. In a competitive global economy, these individually set goals prevent countries from reaching the global agreement that will be the key to future emissions reductions.

The implementation of a universal measure for all countries has not occurred, mainly because of two ongoing debates: 1) between developing countries and developed countries on historical responsibility, in terms of the cumulative emissions and land use of the developed countries; and 2) on the transfer of the technology required to improve production efficiency and to reduce the emissions of developing countries. Our proposed measure, MGHG-INT, provides a unified view of all the countries involved, and eliminates any debate on the differences between them:

- Production vs. consumption: It seems that the major difference between developing countries and developed countries is in their production and consumption habits. The proposed MGHG-INT uses the term activity instead, and so covers both production and consumption in a universal way.
- Historical (cumulative) emissions levels: The issue of the cumulative footprint of countries is addressed and discussed in section B of the appendix. In brief, it has been observed that, on a scale of one decade, the cumulative impact is, in fact, less than 1 percent. We will therefore ignore it in the main part of this work.
- Historical emissions (land use): The proposed measure does not consider land-use emissions (and de-emissions). We suggest that these emissions be submitted to the proposed global emissions trading system (ETS), as discussed in section 5.2. The developing countries are allowed to produce land-use emissions. However, they cannot clear their GHG emissions before clearing their land use emissions.
- Technology transfer: it seems that technology transfer, in the form of adapting best practices, could boost the movement toward a greener earth if a suitable control mechanism is implemented. This is beyond the scope of this work, but will be considered in the future by proposing technological leapfrogging for developing countries [44, 12] while respecting intellectual property rights.

2.2 Threats: De-industrialization of Europe

While there has been much debate and discussion on whether or not the European emissions reduction policy has accelerated Europe's de-industrialization [36], it is obvious that a high volume of manufactured goods is flowing from the BRICS countries (Brazil, the Russian Federation, India, China, and South Africa) to Europe [5]. In particular, some industries are facing carbon leakage through so-called competitiveness channel [26]. For example, a high rate of leakage has been detected in the steel and cement industries [10, 28]. In terms of European de-industrialization, many parameters, such as fewer work hours and high unemployment rates (the effect of an aging population), have been mentioned as key factors [5]. However, the advantages of low wages and low prices of the BRICS countries, as well as the use of unpenalized non-green energy sources, may also be factors [5, 3]. The de-industrialization of Europe, if it exists, may accelerate the increase in global GHG emissions, because it moves the industries it loses to those regions of the world that have very little or no environmental supervision. As a result, in a competitive global economy, more non-green energy will be generated from low-cost, non-green sources.

At the same time, it is argued that climate change discussions are overly focused on its environmental impacts, and ignore its socio-economic consequences [3]. As mentioned in the previous subsection, a uniform and universal emission control policy can address this deficiency, and enable all global players to pursue their economical growth in a sustainable way. We that hope that the MGHG-INT, which we introduce in the next section, and our proposed Carbon Border Tax (CBT) and ETS can form the basis for such a global emission control policy.

2.3 Threats: Leakage and hidden emissions in exports/imports and transport

Although a number of European countries have been able to work toward their commitments on emission reduction within the Kyoto protocol, it has been observed by many researchers that some of this reduction has been accomplished by outsourcing the emissions to other countries [36]. For example, in [49], using a UK-specific multi-region input-output (MRIO) model, it has been observed that the net CO_2 emissions embedded in UK imports increased from 4.3% of producer emissions in 1992 to a maximum of 20% in 2002. The total estimated UK carbon footprint in 2004 was 730 Mega tonnes of carbon dioxide (MtCO2) and 934 Mega tonnes of carbon dioxide equivalent (MtCO2e) for all GHGs [49]. It has also been observed that one-third of China's emissions are related to goods to be exported [47], and globally 23% of CO_2 emissions from the burning of fossil fuels is used in the production of goods that were consumed in a different country [9]. This suggests that consumption-based emission analysis should be performed, in order to see and control hidden carbon leakage [9]. However, as mentioned above, consumption-based analysis cannot cover all countries, and so we argue that analysis should be based on activities, as we explain in section 3.

2.4 Threats: Population

Population growth alone is a threat to the earth's sustainability. Any measure that promotes an increase in the world's population should be avoided, and so, because of population growth, the measure of GHG emissions per capita is a dangerous one. Instead, in this work, a measure of the activity of a population based on its level of development is used. In our calculations, we use a snapshot of the population in a reference year (1980 in our case, as it is the year of our earliest data). Among a number of global human development measures, the Inequality-adjusted Human Development Index (IHDI) is well-known and accepted (see section A.3 of the appendix for details). We multiply the IHDI by the population snapshot, and use that figure in the calculation, instead of the current population (see section 3).

2.5 Threats: Administration cost

One of parameters that is used to avoid the adoption of an emission control policy is administrative cost. Unlike a traditional carbon border tax, whose associated administrative costs could be as high as a proportion of price of goods [31], our solution, which is independent of any particular product, targets a country as a whole. Now, a country's bureaucracy is responsible for implementing mechanisms to reduce their total emissions (perhaps implementing a small scale of our solution within their country, as will be discussed in subsection 5.3). If it fails to do so, the country will face the migration of industries and markets to other regions of the world with more efficient infrastructure and better emission reduction policies.

A firm could argue that it is producing a small-footprint product in a country with a large footprint, and therefore the carbon tax calculated for this country is unfair to the firm. However, it should be taken into account that this firm has a hidden footprint associated with its employees. In a firm with 10,000 employees, there could be 50,000 or so residents, including extended family members, living a non-green lifestyle in a country with an inefficient infrastructure. At the same time, it is worth noting that the average footprint of an employee in a firm in a developing country should be considered to be several times larger than the footprint per capita of that country, because of the high degree of social inequality in these countries.

2.6 Data

In this work, we use the CO_2 and non-CO_2 emissions data over a period of 30 years from 1980 to 2009. These data were obtained from the US Energy Information Administration and World Bank databases [1]. The economic and social indicators, such as GDP at purchasing power parity exchange rates (PPP) [13], population, and the IHDI [2, 11], were obtained from the United Nations Statistics and Research Database (UNdata), the International Monetary Fund (IMF), and the United Nations Development Programme (UNDP) database covering the same period of time. The Green and Red scenarios, which will be referred to in section 4, were built based on the B1 Asian-Pacific Integrated Model (AIM) and the A1B AIM scenarios of the Intergovernmental Panel on Climate Change (IPCC) [29, 32, 8, 17, 22, 23, 24, 7, 18, 19, 20, 21] referred to in section A.4 of the appendix. For more information on the data and the source links are given in the notation section (section A of the appendix).

The use of names of countries in the figures and tables serves only to identify world regions, and does not imply the expression of any opinion on the legal status of any country or its authorities, or concerning its boundaries.

3 Modified GDP (MGDP) and Modified GHG Emission Intensity (MGHG-INT)

The GHG-INT of a country is defined as the ratio of its emissions to its GDP:

$$\mathrm{GHGINT}_{i,y} = \frac{\mathrm{EM}_{i,y}}{\mathrm{GDP}_{i,y}} \tag{1}$$

where $\mathrm{GHGINT}_{i,y}$ is the GHG-INT of country i in year y, and $\mathrm{EM}_{i,y}$ is the total emissions of that country in the same year (excluding land-use emissions). This measure provides the GHG footprint of countries based on their productivity. If the GHG emissions of a country are proportional to its GDP, then this measure is acceptable for that country. In contrast, if the amount of GHG emissions is relatively higher than the GDP of a country, then that country is designated a red emissions zone according to this measure. For example, if a less productive country with a small GDP is producing a large amount of GHG gases, then its GHG-INT is not acceptable. According to the GHG-INT measure, countries like the United States with very high GHG emissions and a high GDP are safely in the green zone, while countries like China with high

GHG emissions, but not a correspondingly high GDP are in the red zone. Of course, countries like China with a large population prefer to use a different measure, which is a ratio of emissions to the population (GHGpCapita):

$$\text{GHGpCapita}_{i,y} = \frac{\text{EM}_{i,y}}{\text{Capita}_{i,y}} \tag{2}$$

where $\text{GHGpCapita}_{i,y}$ is the GHGpCapita of country i in year y, and $\text{Capita}_{i,y}$ is its population. This measure represents the GHG footprint of a country based on its population. For a country with GHG emissions that are proportional to its population, GHGpCapita is an acceptable measure, but if the amount of its GHG emissions is relatively more than the size of its population, then that country is in the red zone. For example, if a small country with a small population produces a large amount of GHG gases, it will not find the GHGpCapita an attractive measure. According to the GHGpCapita, countries like China, with very high GHG emissions and a large population, are in the green zone. In contrast, countries like the United States, with high GHG emissions but a relatively small population, are in the red zone.

To arrive at a universal GHG emissions measure which is robust with respect to variations in GDP and population, but works for all countries, we modify the GHG-INT, and redefine it as the ratio of emissions to "activities":

$$\text{MGHGINT}_{i,y} = \frac{\text{EM}_{i,y}}{\text{``activities''}_{i,y}} \tag{3}$$

where $\text{MGHGINT}_{i,y}$ is the modified GHG intensity measure of country i in year y (defined above), and $\text{``activities''}_{i,y}$ is the activity of that country (explained below) during the same period. Here, "activities" replaces GDP in Equation (1). We model them as a modified version of GDP (MGDP), which not only includes the production of a country (its GDP), but also considers the internal activity of its population. We formally introduce the MGDP later in this work.

Using the MGDP, we define MGHG-INT as follows:

$$\text{MGHGINT}_{i,y} = \frac{\text{EM}_{i,y}}{\text{MGDP}_{i,y}} \tag{4}$$

where $\text{EM}_{i,y}$ represents the total GHG emissions of that country, except for the land-use CO_2 emissions.

Table 2
The IHDIxCapita in 2009: a) for the top 5 countries, b) for COI. Note: The 1980 population snapshots were used in the calculation of IHDIxCapita

Let us start first with IHDIxCapita. The IHDIxCapita is defined as the product of the UN Development Programme's IHDI and the population snapshot (see section A.3 for further detail):

$$\text{IHDIxCapita}_{i,y} = \text{IHDI}_{i,y}\text{Capita}_{i,1980} \tag{5}$$

where $\text{IHDI}_{i,y}$ and $\text{Capita}_{i,1980}$ are the IHDI and population snapshot of country i, and $\text{IHDIxCapita}_{i,y}$ is the IHDIxCapita of the same country in year y. The countries with highest IHDI and IHDIxCapita are listed in Tables 1 and 2. The balanced IHDIxCapita is defined as the IHDIxCapita normalized to the maximum IHDIxCapita in the same year, scaled to the maximum GDP (PPP) of the same year:

$$\text{IHDIxCapita}^{\text{BAL}}_{i,y} = \text{GDP}^{\text{MAX}}_{y}\frac{\text{IHDIxCapita}_{i,y}}{\text{IHDIxCapita}^{\text{MAX}}_{y}} \tag{6}$$

where $\text{IHDIxCapita}_{i,y}$ is the IHDIxCapita of country i in year y, and $\text{IHDIxCapita}^{\text{MAX}}_{y}$ and $\text{GDP (PPP)}^{\text{MAX}}_{y}$ are the maximum of the IHDIxCapita and the maximum of GDP (PPP) of all countries in year y respectively. The balanced GDP, $\text{GDP}^{\text{BAL}}_{i,y}$, is the ratio of the GDP (PPP) to the GDP (PPP) of the country with the IHDI of $\text{IHDIxCapita}^{\text{MAX}}_{y}$, scaled to the maximum GDP of the same year:

$$\text{GDP}^{\text{BAL}}_{i,y} = \text{GDP (PPP)}^{\text{MAX}}_{y}\frac{\text{GDP (PPP)}_{i,y}}{\text{GDP (PPP)}^{\text{IHDI}}_{y}} \tag{7}$$

where GDP $(\mathrm{PPP})_{y}^{\mathrm{IHDI}}$ is the GDP (PPP) of the country with the IHDI of $\mathrm{IHDIxCapita}_{y}^{\mathrm{MAX}}$.

With this definition, if we calculate the balanced GDP of the country with the maximum IHDIxCapita, we obtain the GDP (PPP) of the country with the maximum GDP. Also, the balanced IHDIxCapita of a country with the maximum IHDIxCapita is again the GDP (PPP) of the country with the maximum GDP. In this way, both the balanced GDP and the balanced IHDIxCapita are normalized to the same level, and therefore it is possible to average them and calculate the MGDP. The MGDP is defined as follows:

$$\mathrm{MGDP}_{i,y} = Z\frac{\mathrm{GDP}_{i,y}^{\mathrm{BAL}} + \mathrm{IHDIxCapita}_{i,y}^{\mathrm{BAL}}}{2} \tag{8}$$

where $\mathrm{MGDP}_{i,y}$ is the MGDP of country i in year y, and $\mathrm{IHDIxCapita}_{i,y}^{\mathrm{BAL}}$ and $\mathrm{GDP}_{i,y}^{\mathrm{BAL}}$ are the balanced IHDIxCapita and the balanced GDP of that country in year y respectively. The normalization parameter Z is selected is such a way that the world MGDP in 1990 is equal to the world GDP (PPP) in the same year.

If a country has a GDP (PPP) higher than GDP $(\mathrm{PPP})_{y}^{\mathrm{IHDI}}$, it will have a $\mathrm{GDP}^{\mathrm{BAL}}$ higher than the GDP $(\mathrm{PPP})_{y}^{\mathrm{MAX}}$. At the same time, the balanced IHDIxCapita is the ratio of the IHDIxCapita to the maximum IHDIxCapita, scaled to GDP $(\mathrm{PPP})_{y}^{\mathrm{MAX}}$. Every country has an IHDIxCapita lower than the maximum IHDIxCapita, and therefore it will have a balanced IHDIxCapita that is lower than GDP $(\mathrm{PPP})_{y}^{\mathrm{MAX}}$.

The advantage of the MGDP over the GDP is that countries with a large population and those with a high GDP are treated the same way, and benefit from this measure. For countries with high GDPs, the balanced GDP is high, and for countries with a large population and a good IHDI factor, the balanced IHDIxCapita is high. In both cases, the MGDP is high, and therefore their footprint, MGDG-INT, will be small. But, if a country suffers from with a low GDP, or a large population but low quality of life, then both $\mathrm{GDP}^{\mathrm{BAL}}$ and $\mathrm{IHDIxCapita}^{\mathrm{BAL}}$ will be low, which results in a high MGHG-INT value, and indicates that the emissions of that country should be reduced.

The countries with the highest MGDP values are listed in Table 3. These values are compared with those of countries with the highest GDP. We can conclude that the MGDP is a better measure, as it gives a more balanced picture of a country's activities status. The distributions of the MGDP and the GDP per capita are illustrated in Figures 4(a) and 4(b) respectively.

It is interesting to compare the variations in GDP (PPP) and MGDP variation over time. Figure 5 shows the profiles of GDP (PPP) and MGDP over three decades. It is worth noting that the MGDP shows a very stable and smooth increase compared to from the bubbling effect of the GDP (PPP). This stability can be put down to the fact that the MGDP is normalized to the population activities that are less dependent on the market fluctuations. The global MGDP has grown by 1.67% annually over the last 30 years. This suggests that it can also be used in other economic analyses as a robust measure.

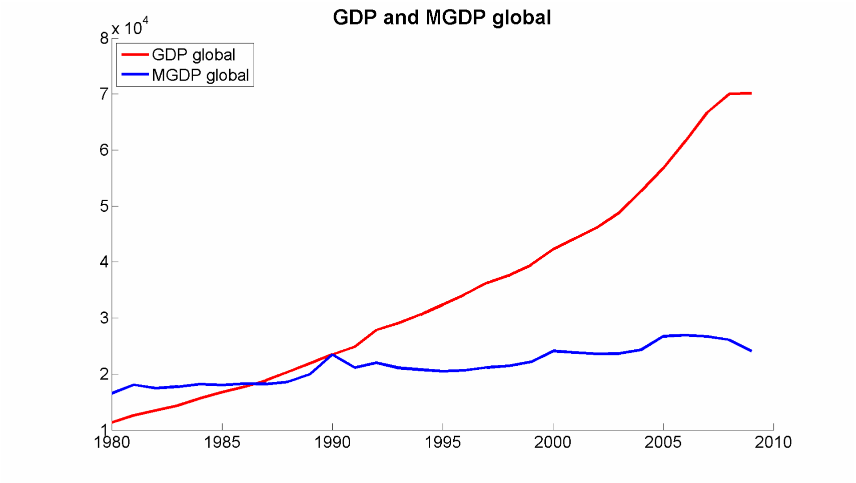

Fig. 5. A comparison between global GDP and global MGDP over three decades. The MGDP shows very robust and stable growth.

Finally, a comparison of the various indicators for two major global players, the United States and China, is provided in Figure 6. In Figure 6(a), the variations in GHG-INT and MGHG-INT are compared. As we can see, GHG-INT and GHGpCapita are too far apart for either of the two countries to catch up with the other, and this has been resulted in disagreements in the past. However, the MGHG-INT values are close, and so the two countries could converge the values with a reasonable effort. In Figure 6(b), the GDP and MGDP of the two countries are compared. Again, the MGDP shows the competitiveness between the countries, and gives a better picture of their economies.

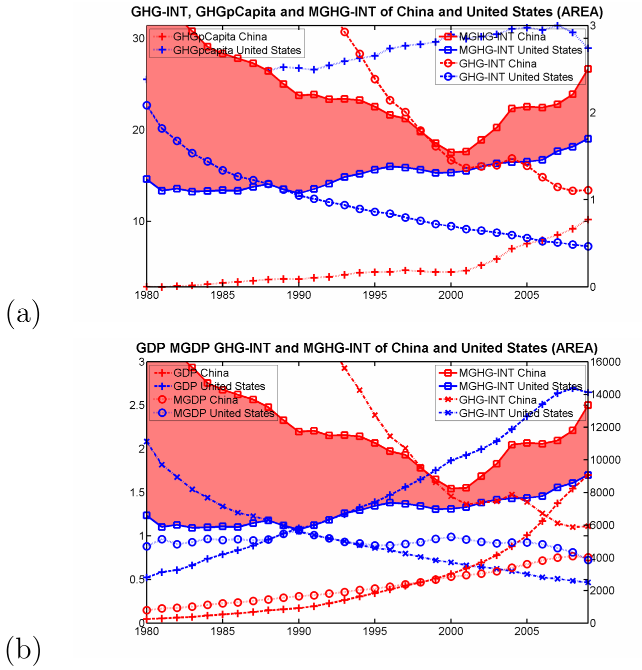

Fig. 6. a) A comparison between the GHG-INT, GHGpCapita, and MGHG-INT of China and the United States over three decades. b) The same comparison as in (a), but with respect to GDP, MGDP, GHG-INT, and MGHG-INT.

It is worth noting that the MGDP dollar is similar to the international GDP (PPP) dollar, but not the same. The MGDP dollar cannot be exchanged with any currency, and serves only as a global and uniform measure for comparing all countries, regardless of their status in the world.

The global distribution of MGHG-INT is provided in Figure 10(a). As expected, all major emitters have a high MGHG-INT. The same distribution is shown in Figure 10(b), but limited to China's MGHG-INT, in order to provide a more detailed presentation. The countries with highest MGHG-INT are also listed in Table 4.

Rank	**Country**	**MGHG-INT**
1	Zimbabwe	7.21
2	Turkmenistan	6.41
3	Zambia	5.39
4	Congo, DRC	4.99
5	Bahrain	4.99

(a)

The MGHG-INT in 2009: a) for the top 5 countries, b) for COI.

Although the MGHG-INT will provide a universal measure of the footprint potential at the international level, and can be used by investors to choose

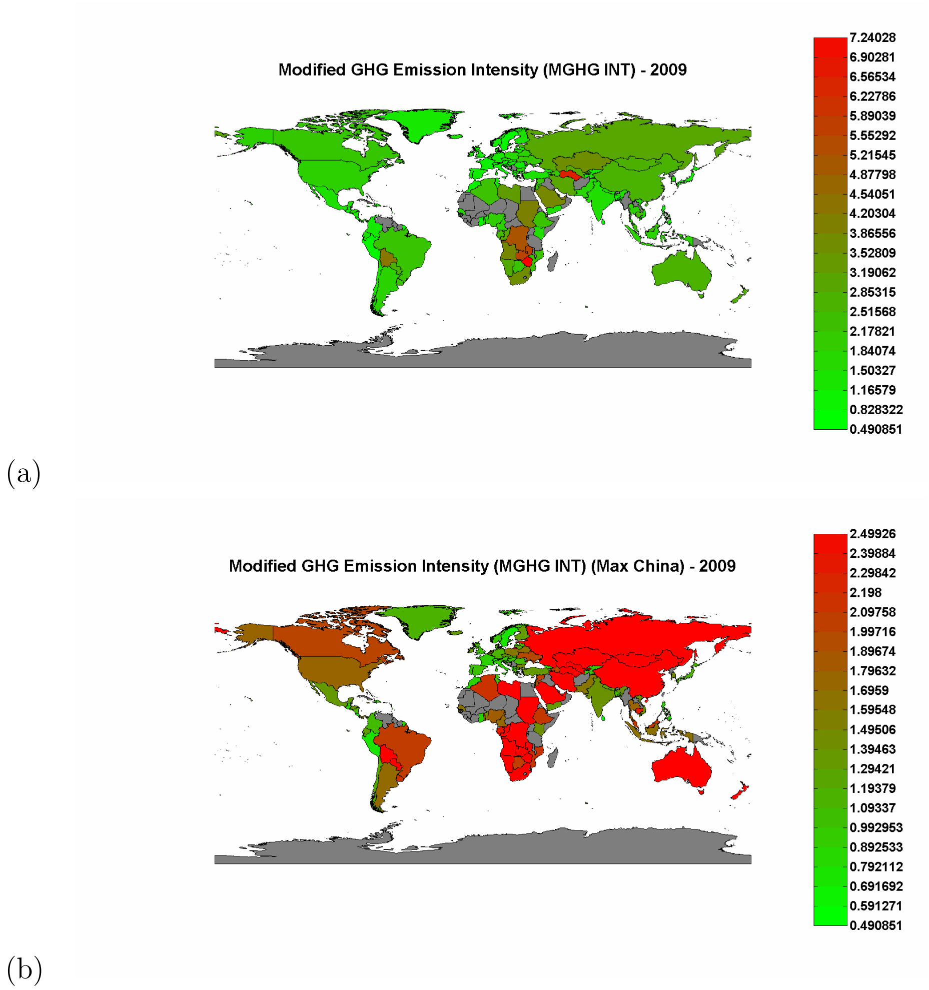

Fig. 7. a) The MGHG-INT distribution over the world in 2009. b) The same as (a), but with the maximum value of China's MGHG-INT, in order to provide a clearer picture. As discussed in the section on motivations, the MGHG-INT provides a universal measure of GHG emissions for all countries.

a region with higher efficiency and less risk of penalties, it cannot be used to directly calculate those penalties or the adjustments required to reduce emissions. The MGHG-INT concept is analogous to the power concept in a machine. The penalty should be applied based on the amount of energy the machine consumes, rather than on its power specifications. In the next section, the percentage of 'non-greenness' of the production of each nation is calculated using the MGDP and MGHG-INT. This percentage will serve as the foundation for a carbon tax, which will be introduced in section 5.

4 RED Percentage: A Measure of Emission Inefficiency

In this section, we describe two GHG emission scenarios, Green and Red, representing safe (admissible emissions) and dangerous (100% over-emissions) levels for the world respectively. The Green emission scenario is based on the IPCC's B1 Asian-Pacific Integrated Model (AIM) scenario [29, 20] (see section A.4 for more details). We denote the Green scenario emissions in year y by $\mathrm{GB1}_y$. We use the A1B AIM scenario as the base for building the Red scenario, denoted by $\mathrm{RA1B}_y$ (see section A.4). We distribute $\mathrm{GB1}_y$ among all countries based on their MGDP, in order to calculate the green or B1 AIM share of each country:

$$\mathrm{ADMEM}_{i,y} = \frac{\mathrm{MGDP}_{i,y}}{\mathrm{MGDP}_y}\mathrm{GB1}_y \tag{9}$$

where $\mathrm{MGDP}_{i,y}$ is the MGDP of country i in year y, $MGDP_y$ is the total MGDP of the world, $\mathrm{GB1}_y$ is the global green admissible emissions in year y, and $\mathrm{ADMEM}_{i,y}$ is the admissible (B1 AIM share) emissions of country i in year y. If the difference between the total emissions of a country and its green (B1 AIM) share is negative, then all its emissions are admissible, and the difference will be considered as the emission credits for that country:

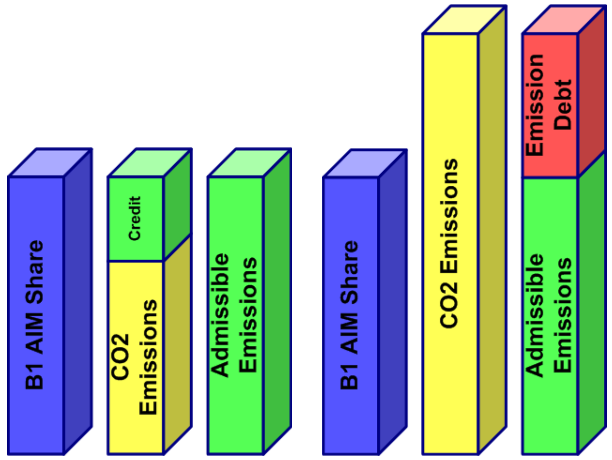
$$\mathrm{EMCRD}_{i,y} = \begin{cases} -\left(\mathrm{EM}_{i,y} - \mathrm{ADMEM}_{i,y}\right) & \text{if } \mathrm{EM}_{i,y} - \mathrm{ADMEM}_{i,y} < 0 \\ 0 & \text{otherwise} \end{cases} \tag{10}$$

where $\mathrm{EMCRD}_{i,y}$ represents the emission credits of country i in year y, and $\mathrm{EM}_{i,y}$ is the total emissions of that country in the same year. But, if the total emissions of a country are greater than its green share (its admissible emissions), the difference is the emission debt for that country:

$$\mathrm{EMDBT}_{i,y} = \begin{cases} \left(\mathrm{EM}_{i,y} - \mathrm{ADMEM}_{i,y}\right) & \text{if } \mathrm{EM}_{i,y} - \mathrm{ADMEM}_{i,y} > 0 \\ 0 & \text{otherwise} \end{cases} \tag{11}$$

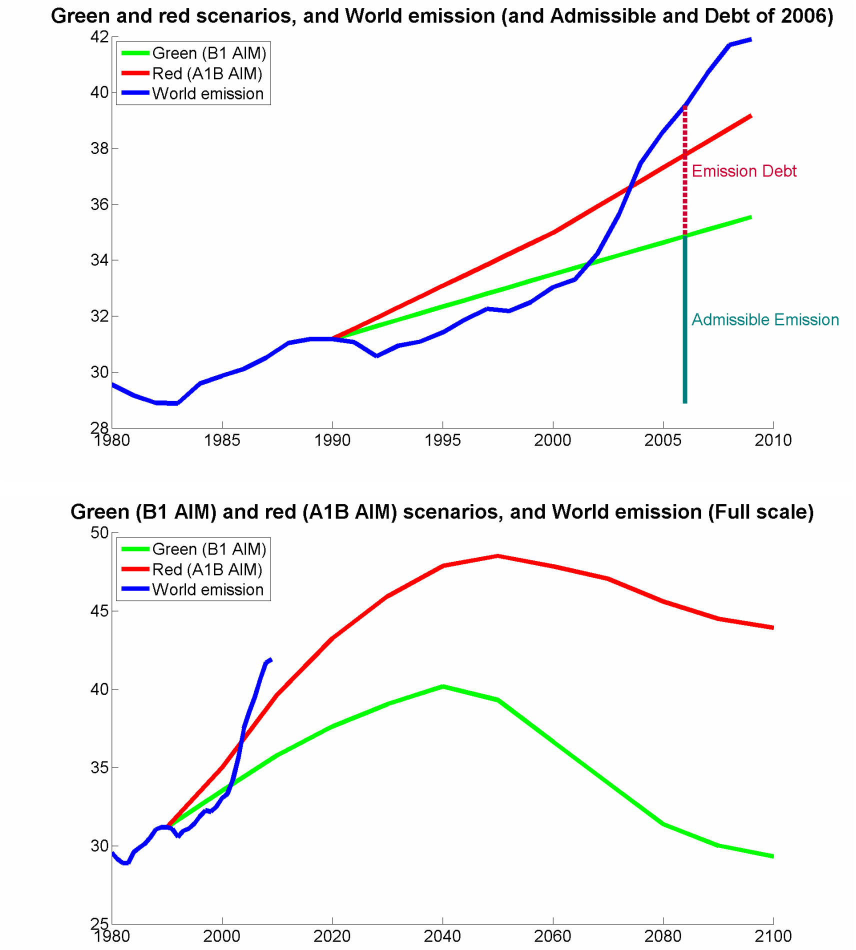
where $\mathrm{EMDBT}_{i,y}$ is the emission debt of country i in year y.

These concepts are illustrated in Figure 8. In Figure 8(a), the country's total emissions are less than its admissible emissions (ADMEM), and therefore it has some emission credits (EMCRD), which can be traded in the proposed ETS (see section 5.2). In contrast, in Figure 8(b), the country is in emission debt, because its total emissions are more than that of its B1 AIM share. In this case, a carbon tax will be imposed on the goods originating from that country (see section 5.1), except in the case that country clears its emission debt in the ETS.



(a) (b)

Fig. 8. An illustration of the emission credits and emission debt concepts: a) a country with positive emission credits. b) a country with positive emission debt.



(a)

(a)

Fig. 9. a) An illustration of the admissible emission and the emission debt concepts. b) The long-term trends of our Green and Red emissions scenarios (based on the B1 AIM and A1B AIM scenarios).

In Table 5, the 5 countries with the highest and lowest admissible emissions are listed. In Table 6(a) and Table 6(b), the 5 countries with the highest emission debt and the highest emission credits are listed respectively. It is interesting that the countries with the most emission credits are in Europe, and can be connected to the EU emission reduction programs.

Rank	Country	Admissible Emissions (MtCO2e)
1	**China**	**6076.96**
2	**United States**	**5841.83**
3	**India**	**2743.42**
4	**Japan**	**1720.15**
5	**Germany**	**1320.93**

Rank	Country	Admissible Emissions (MtCO2e)
1	Tonga	0.46
2	Comoros	0.76
3	Solomon Islands	0.89
4	Cape Verde	1.06
5	Maldives	1.31

Table 5

Rank	Country	Emissions Debt (MtCO2e)
1	**China**	**3986.16**
2	**United States**	**738.84**
3	**Brazil**	**348.86**
4	Saudi Arabia	312.16
5	Iran	311.54

Rank	Country	Emissions Credit (MtCO2e)
1	**Japan**	**481.89**
2	France	419.23
3	**Germany**	**380.40**
4	United Kingdom	345.82
5	Italy	344.81

Table 6
a) The 5 countries with highest emission debt. b) Top 5 countries with highest emission credits.

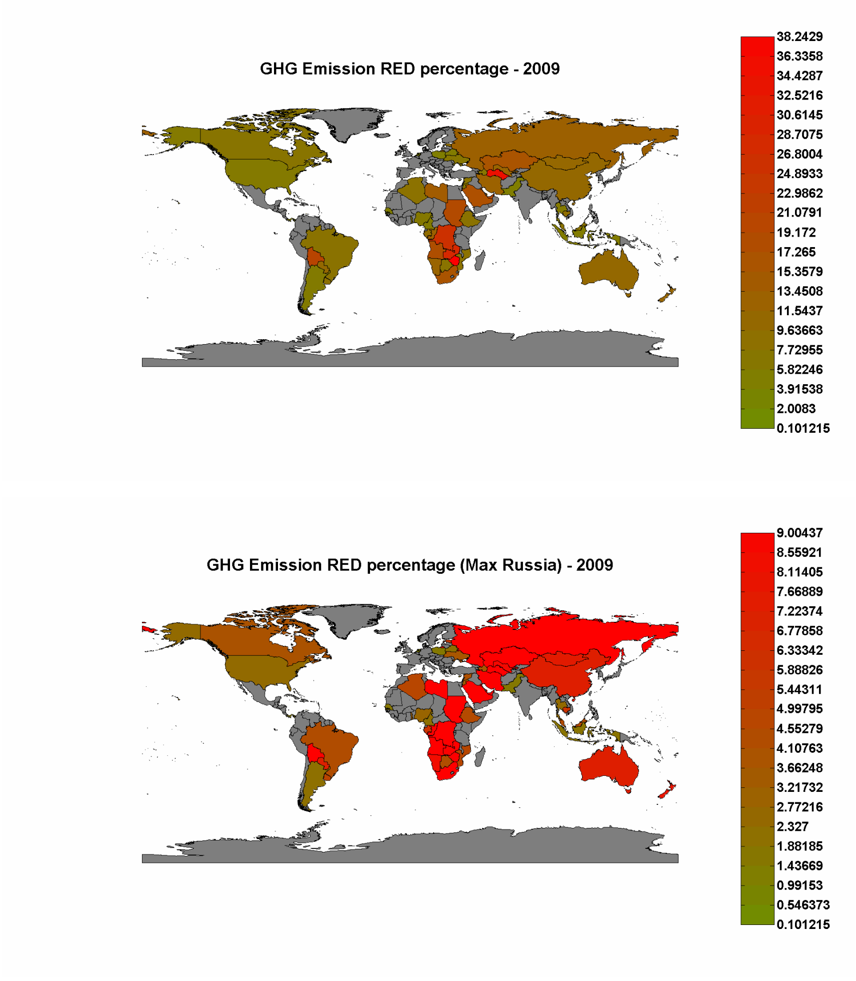
The concepts of emission debt (EMDBT) and emission credits (EMCRD) allow us to define a percentage of non-greenness for each country, which we call the RED percentage. To do so, we use the Red emission scenario, which is based on the A1B AIM scenario, in order to define the projection interval, based on the assumption that the Green emission scenario (B1 AIM) represents the 0% level, and the Red emission scenario (A1B AIM) the 100% level. We calculate the RED percentage as follows: first, we define the global emission debt margin as the difference in the amount of emissions of the A1B AIM and B1 AIM scenario; then, we calculate the emission debt margin of a country as a linear fraction of the admissible emissions:

$$\mathrm{EMDBT}_{i,y}^{\mathrm{MARG}} = \frac{\mathrm{ADMEM}_{i,y}}{\mathrm{GB1}_y} \left(\mathrm{RA1B}_y - \mathrm{GB1}_y\right) \tag{12}$$

where $\mathrm{EMDBT}_{i,y}^{\mathrm{MARG}}$ is the emission debt margin of country i in year y. From this, the RED percentage can be easily defined as:

$$\mathrm{RED}_{i,y} = 100 \frac{\mathrm{EMDBT}_{i,y}}{\mathrm{EMDBT}_{i,y}^{\mathrm{MARG}}} \tag{13}$$

where $\mathrm{RED}_{i,y}$ is the RED percentage of country i in year y. Automatically, the RED percentage will be 0% for a county without any emission debt. The distribution of the RED percentage over the world is shown in Figure 10. In order to make the variations over the map more visible, this distribution has been redrawn in Figure 10(b), considering Russia's RED percentage as the maximum value. The countries with a 0% RED percentage are shown in gray (also shown in gray are countries that do not have a RED percentage because they have no IHDI index).



(a)

(b)

Fig. 10. a) The RED percentages distribution over the world in 2009. b) The same as in (a), but with Russia's RED percentage as a maximum for better visualization. The percentages are divided by a factor of 100.

The top 20 countries in terms of the RED percentage are listed in Table 7. This percentage shows by how much a country is over-emitting relative to its emission debt margin. For example, a country with a RED percentage of 470% has an emission debt 4.7 times higher than its emission debt margin. In the next section, we use the RED percentage as the reference for imposing a carbon border tax.

The trend of the B1 AIM share and the A1B AIM share, and the emissions of four countries are shown in Figure 11. The China is an example of a country that has exceed both Green and Red emission shares, its RED percentage being more than 500%. Belgium is an example of a European country that is within its Red (A1B AIM) emission share, but has exceeded its Green (B1 AIM) share. Its RED percentage was less than 100% in 2009. At the other end of the scale, we have Japan, whose emissions are below its Green (B1 AIM) share. The RED percentage for Japan was 0% in 2009 and previous years. The last example is the United States. The impact there of the economic crisis not only on the emissions, but also on its Green and Red shares can easily be seen in Figure 11(d).

Rank	**Country**	**RED %** ($\times 10^2$)
1	Zimbabwe	36.36
2	Turkmenistan	31.23

5 Carbon Tax and Emissions Trading

In this section, we introduce a Carbon Border Tax (CBT). Because of the highly competitive nature of the global market, we use a weak version of the RED percentage as the carbon tax. To do this, we define the CBT on the goods of country i as:

$$\mathrm{CBT}_{i,y} = \mathrm{RED}_{i,y}/\mathrm{RED}_{\mathrm{CBT}} \tag{14}$$

where $\mathrm{CBT}_{i,y}$ is the carbon border tax percentage on the goods of country i in year y, and $\mathrm{RED}_{\mathrm{CBT}}$ is the weak conversion factor from the RED to the CBT. We chose a value of 100 for $\mathrm{RED}_{\mathrm{CBT}}$ in this work to keep the CBT under the global annual growth. For example, for the United States, based on an $\mathrm{RED}_{\text{United State},2009} = 121.09\%$, the CBT on American goods would have been 1.21% in 2010. It is interesting to note that, among the COI, the United States has the lowest CBT (excluding countries with a zero CBT). This means that the they can impose a CBT on the goods of any other country whose CBT is higher than their own, even before an equivalent internal carbon tax is established. It could, for example, have imposed a CBT of $6.28\% - 1.21\% = 5.07\%$ on Chinese goods in 2010, which was the difference between the CBTs of the two countries at the time. In the following section, the impact of this tax on world emissions is analyzed by comparing two scenarios.

5.1 Carbon tax on imports

In this section, two scenarios are compared to evaluate the impact of the proposed tax system.

In both scenarios, it is assumed that the annual MGDP growth of a country is linear, with an annual growth calculated on a period of 10 years between 2000 and 2009. For example, the annual MGDP growth of China and the United States is 4.35% and −2.49% respectively. The maximum annual MGDP growth over the same period corresponds to that of Qatar, with an annual MGDP growth of 8.41%. For countries with lower MGDP growth than the average global MGDP annual growth from 1980 to 2009 (which is 1.67%), it is that average global MGDP annual growth that is used in the calculations.

The two scenarios that are compared are the following:

- **CT scenario**: Imposition of the proposed tax, as in Equation (14). In this scenario, it is assumed that imposing this tax will decrease MGDP growth, and at the same time reduce MGHG-INT. It is also assumed that for each 1% of tax imposed in a year, the MGDP will decrease by 0.5%, and the

MGHG-INT improves by 0.5%. It is assumed as well that technological breakthroughs and use of renewable energy will independently improve the MGHG-INT by 1% per year. Therefore, the governing equations of the scenario can be written as follows:

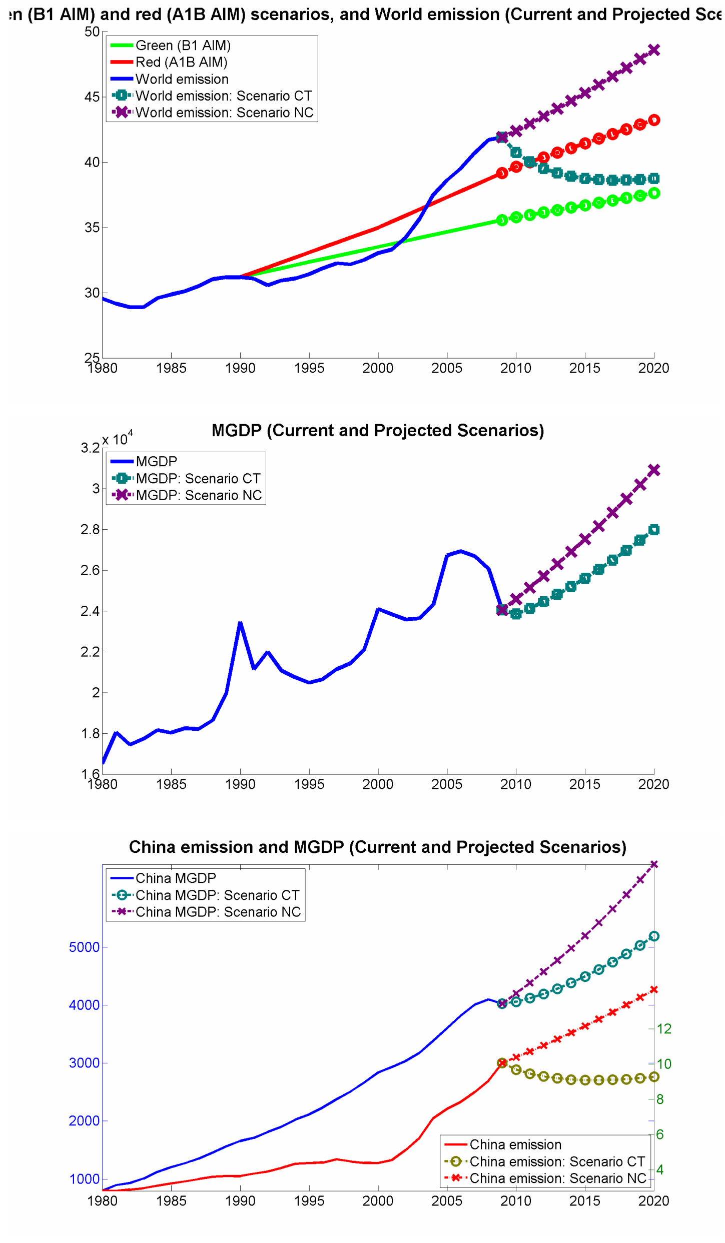
$$\begin{cases} \mathrm{MGDP}_{i,y} = (1+\mathrm{MGDP}'_{i,y-1})(1-0.5\ \mathrm{CBT}_{i,y-1}/100)\mathrm{MGDP}_{i,y-1} \\ \mathrm{MGHGINT}_{i,y} = (1-0.5\ \mathrm{CBT}_{i,y-1}/100-0.01)\mathrm{MGHGINT}_{i,y-1} \\ \mathrm{EM}_{i,y} = \mathrm{MGDP}_{i,y}\ \mathrm{MGHGINT}_{i,y} \\ \mathrm{CBT}_{i,y} = \mathrm{RED}_{i,y}/\mathrm{RED}_{\mathrm{CBT}} \end{cases} \tag{15}$$

where $\mathrm{MGDP}'_{i,y}$ is the annual growth of $\mathrm{MGDP}_{i,y}$, and $\mathrm{RED}_{i,y}$ is calculated based on Equations (9)-(13) in section 4.

- **NC scenario**: No CBT is imposed. However, here too, it is assumed that research and new technologies will improve the MGHG-INT by 1% per year.

$$\begin{cases} \mathrm{MGDP}_{i,y} = (1+\mathrm{MGDP}'_{i,y-1})\mathrm{MGDP}_{i,y-1} \\ \mathrm{MGHGINT}_{i,y} = (1-0.01)\mathrm{MGHGINT}_{i,y-1} \\ \mathrm{EM}_{i,y} = \mathrm{MGDP}_{i,y}\ \mathrm{MGHGINT}_{i,y} \\ \mathrm{CBT}_{i,y} = \mathrm{RED}_{i,y}/\mathrm{RED}_{\mathrm{CBT}} \end{cases} \tag{16}$$

The governing equations are solved over a 10-year period, until 2020, for both scenarios.



(a)

(b)

(c)

Fig. 12. a) The impact of the proposed CBT on global emissions in the short term. In the CT scenario, the tax is implemented, and in the NC scenario, it is business as usual. b) The impact on global economic growth. c) The impact on China's economy and emissions.

In Figure 12(a), the difference between the two scenarios worldwide is depicted. As can be seen, by applying the proposed CBT, the emissions decrease globally, and even fall below the emissions in the Red (A1B AIM) emissions scenario. At the same time, the global economy will be growing, as shown in Figure

12(b). Although the NC scenario shows higher growth in this figure, it is just a projected result and does not take into account the risk of a global downturn resulting from climate change. The impact of the tax on rapidly growing China is presented in Figure 12(c) which shows the emissions and MGDP of China in both scenarios. Again, in the CT scenario, China benefits from high economic growth, while its level of emissions is substantially lower.

COI	tax %
Australia	**6.30**

(b)

Table 8
The proposed carbon border tax for the COI: a) at the beginning of the CT scenario, b) at the end of the CT scenario.

For a better understanding of the impact of the CBT, the taxes of the COI at the beginning and end of the CT scenario are compared in 8. There is a definite decrease in all the taxes. It is worth noting that, in spite of global convergence toward the B1 AIM limit, they are still non-zero, because of the large proportion of these countries that are in global emission debt. In future work, we will confirm the results of these scenarios using MRIO models.

5.2 Global Emissions Trading System

	Emission (MtCO2e)
World Emissions	40686.10
Green (B1 AIM) Limit	34678.59
Red (A1B AIM) Limit	38300.59
Total Allowed Emissions	34678.59
Total Emission Debt	7971.64
Total Emission Credit	4000.34
Total Unrecoverable Emission Debt	3971.30

Table 9
A Overview of global emissions in 2009.

In Table 9, the overall status of the world with respect to emissions, emission credits, and emission debt in 2009 is provided. The total unrecoverable emission debt is the difference between the total emission debt and the total emission credits. As can be seen from the table, there is a huge amount of unrecoverable emission debt (around 3971.30 MtCO2e in 2009), which means that there is a great deal of demand in the proposed emissions trading system, which will in turn lead to higher prices for emission credits. This will encourage countries to increase their emission credits not only to reduce their carbon tax, but also to sell it in the global ETS. Therefore, a emission trading system at the international level for emission credits and emission debt will be very active. Countries with high debt will buy credits to reduce their RED percentage, and consequently the carbon tax on their goods.

We propose that land-use emissions should be first cleared in the ETS. In other words, a country with a debt in land-use emissions cannot buy emission credits for its emission debt before clearing its land-use emission debt. In this way, land-use emissions are neither promoted nor ignored, and it is left to individual countries to choose between land use and industrial development. It seems that a cumulative trading mechanism is required to maintain stability in the system and keep track of emissions.

5.3 Carbon tax within a country

A similar model as Equation (14) can be designed as a carbon tax system within a country. Such a system could be modeled on provincial or corporate slices. However, this discussion is beyond the scope of this work.

5.4 Emission trading system within a country

We suggest injecting the revenue from the CBT in each country into the growing of green initiatives. However, we recommend targeting the revenues in each sector to green industries in the same sector.

In terms of uncertainty in the data used, it has been observed that emissions at the international level are associated with a very low level of uncertainty [48, 16]. There are two possible reasons for this. One is the fact that a nation's emissions represent the sum of many small contributions from various sectors that may be unrelated. This lack of correlation can result in the cancellation of uncertainties. The second is that the total consumption or production of a sector can more easily be calculated than the composition of that consumption.

6 Conclusion and future prospects

A modified GHG intensity (MGHG-INT) measure at the international level is introduced in this work. This measure, which is based on a modified GDP (MGDP) indicator, can be used to compare the emissions footprint of all nations, regardless of their place in the world economy. The MGDP is obtained by combining the GDP and IHDI scores of countries, in order to account for all their activities. Using this universal measure, the non-greenness of the goods of each country is calculated in the form of its RED percentage. Then, a carbon border tax (CBT), along with a global ETS, are proposed. The impact of the proposed tax is analyzed over a period of one decade with promising results, in terms of the reduction in emissions, while preserving reasonable global growth. Land-use emissions are directed to the ETS in order to avoid any disagreement on the historical land-use emissions.

In future work, we will confirm the results of the proposed CBT scenario using an MRIO model. The impact of the variable $\mathrm{RED}_{\mathrm{CBT}}$ conversion factor will be studied. Also, we think that the IHDI scores reported for some counties are higher than they should be, and so linearization of these scores in order to better reflect the differences in countries' development will be considered. At the same time, the impact of adding the imported emissions to the internal emissions of a country will be studied. Including these emissions will help encourage countries with a high volume of imports to purchase low-emission goods.

A Notations and Basic Concepts

A.1 Gross Domestic Product (GDP) and Purchasing Power Parity GDP (GDP (PPP))

Gross Domestic Product (GDP), which was first developed by Simon Kuznets for a US Congress report in 1934 [27], is a measure of the market value of all final goods and services produced in a country in a given period. In our calculation, we use the GDP at purchasing power parity exchange rates (GDP (PPP)) as a measure of the activity level of a country, because it reflects living standards more accurately than exchange rates. The GDP (PPP) attempts to relate changes in the nominal exchange rate between two countries currencies to changes in those countries price levels [42]. We use the values calculated by the International Monetary Fund [1] in international dollars. The 5 countries with highest GDP (PPP) in 2009 are listed in Table A.1.

Rank	Country	GDP (PPP)
1	United States	14119.05
2	China	9057.38
3	Japan	4107.04
4	India	3644.53
5	Germany	2814.01

(a)

Rank	Country	Population $\times 10^6$
1	China	987.05
2	India	692.64
3	United States	227.62
4	Indonesia	148.04
5	Russia	141.90

(b)

Rank	Country	Emissions (MtCO2e)
1	China	10063.12
2	United States	6580.66
3	India	2432.10
4	Brazil	1385.17
5	Japan	1238.26

(c)

Top 5 countries in terms of: a) GDP (PPP) in 2009. b) 1980 population snapshot. c) energy-related CO_2 emissions in 2009.

A.2 CO_2 Emissions and GHG Emissions

As mentioned in the introduction, we only consider energy-related CO_2 emissions in the carbon tax calculation. These data, which were retrieved from

---

[1] http://www.imf.org/external/pubs/ft/weo/2011/01/weodata/index.aspx

US Energy Information Administration databases[2], were gathered over the 30-year period between 1980 and 2009. They are restricted to emissions from fuel combustion. The world profile of CO_2 emissions is shown in Figure A.1.

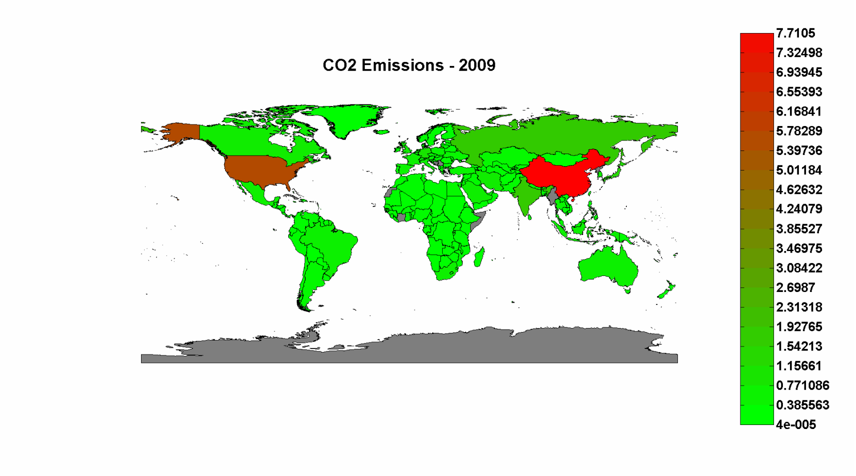

Fig. A.1. CO_2 emissions (for energy and food production) in 2009.

For the other GHGs, the data from the World Bank databases are used. In this study, we consider methane (CH_4) emissions from human activities such as agriculture, and from industrial methane production[3], NO_X emissions from the burning of agricultural biomass, industrial activities, and livestock management[4], as well as HFC, PFC, and SF_6 (HPS) emissions[5] are considered. It is worth noting that these emissions are measured in equivalent gigatonnes of CO_2 (GtCO2e). According to the IPCC's 2001 Third Assessment Report, the Global Warming Potential (GWP) for CH_4 is 23 for a time horizon of 100 years [18]. The GWP for N_2O is estimated to be 296 for the same time horizon. The world profiles in terms of methane, NO_X, and HPS emissions in 2009 are shown in Figures A.2, A.3, and A.4. The total GHG emission distribution across the globe in 2009 in GtCO2e is shown in Figure 1(a) in section 2.

A.3 Human Development Index (HDI) and Inequality-adjusted HDI (IHDI)

As discussed in the section on motivations, we are looking for an independent indicator of national activity in order to modify countries' GDP. We have chosen an indicator based on the Human Development Index (HDI), which is an well-known independent indicator used in the United Nations Development Programme (UNDP) that summarizes human development status [11]. It measures the average achievements of a country in three basic dimensions of human development: a long and healthy life, access to knowledge, and a decent standard of living. The HDI can be seen as a "mean of means", where it first finds the average income achievement, the average educational achievement, and the average health achievement, and then takes the average of the three to obtain the HDI level [2]. The HDI is available from the UNDP and UNdata.

Although the HDI is a promising indicator and considers variations in terms of whether or not goods and services can be bought, it ignores inequalities within a nation. It is reasonable to assume that the level of development is lower in countries with a higher level of inequality. The IHDI is an attempt to address this drawback of HDI [2, 11] [6], and we use it in our calculations as an indicator of national development per capita.

To quantify the total activity level of a nation, we introduce an indicator called HDIxCapita, which is defined as the nation's IHDI multiplied by the its population snapshot. The two activity indicators, GDP (PPP) and HDIxCapita, are combined in a new indicator of activity in section 3, which we call the Modified GDP (MGDP).

A.4 B1 AIM Scenario

As discussed in section 4, we needed two emissions scenarios, which we labeled Green and Red, in order to calculate the RED percentage of nations. Although the choice of these scenarios is arbitrary, we elected to build them based on the IPCC emissions scenarios. The IPCC integrates their B1 environmentally friendly scenarios [32, 8, 17, 22, 23, 24, 7, 18, 19, 20, 21] at the global level. Although they reflect rapid economic growth, these scenarios anticipate equally rapid changes toward a service and information economy. In this way, dematerialization and the introduction of clean technologies will help the world to maintain its economic growth, while giving the environment an opportunity to recover. These B1 scenarios assume that global solutions will be developed for economic, social and environmental stability with improving equity. They see the world's population rising to 9 billion in 2050 and then declining [20]. The same trend is assumed for GHG emissions. Among several models they use, the Asian-Pacific Integrated Model (AIM) [29] is a large-scale computer simulation for scenario analysis of GHG emissions and the impacts of global warming designed for the Asia-Pacific region. This model is linked to a world model, so that global estimates can be made. AIM comprises three main models: the GHG emissions model, the global climate change model, and the climate change impact model [29].

The Green scenario is our environmentally friendly scenario, for which we used the IPCC's[7] B1 AIM scenario data. We distributed the CO_2 emissions accumulated between 1990 and 2100 evenly over the years. In the B1 AIM scenario, the CH_4 emissions peak at 449 Mega tonnes of methane in 2050, which is equivalent to $23\times 449 = 10327$ MtCO2e, and to $100\times(10327/33270) = 31.04\%$ of CO_2 emissions. Similar trends exist for other GHG emissions. Therefore, to define the Green scenario for total GHG emissions, we multiplied the B1 AIM values by 2. Finally, we added the world emissions of 1990 to arrive at an absolute value for Green scenario emissions:

$$\mathrm{GB1}_y = \mathrm{EM}_{\mathrm{world},1990} + 2\left(\mathrm{B1}_y^{\mathrm{AIM}} - \mathrm{B1}_{1990}^{\mathrm{AIM}}\right) \tag{A.1}$$

where $\mathrm{GB1}_y$ is the GHG emissions limit of the Green scenario, $\mathrm{EM}_{\mathrm{world},1990}$ is the world GHG emissions in 1990, and $\mathrm{B1}_y^{\mathrm{AIM}}$ is the B1 AIM scenario CO_2 emissions in year y.

For the Red scenario, we used the same procedure, but with A1B AIM scenario values. The A1B scenarios are a subset of the A1 scenarios that focus more on the balance between fossil fuels and other energy sources. The A1 scenarios, like the B1 scenarios, assume very rapid economic growth and a global population that peaks at mid-century and declines thereafter, along with the equally rapid introduction of new and more efficient technologies. Major underlying themes are convergence among regions, capacity building, and increased cultural and social interaction, with a substantial reduction in regional differences in per capita income. The main difference between the A1 and B1 scenarios is the de-materialization aspect of the B1 scenarios, which see significant changes in economic structures, leading to a service and information economy, with consequent reductions in material-dependent production, and the introduction of clean and resource-efficient technologies [20]. We have built our Red scenario based on the A1 AIM scenario:

---

[7] http://sres.ciesin.org/final_data.html

$$\mathrm{RA1B}_y = \mathrm{EM}_{\mathrm{world},1990} + 2\left(\mathrm{A1B}_y^{\mathrm{AIM}} - \mathrm{A1B}_{1990}^{\mathrm{AIM}}\right) \tag{A.2}$$

where $\mathrm{RA1B}_y$ is the GHG emissions limit of the Red scenario and $\mathrm{A1B}_y^{\mathrm{AIM}}$ is the A1B AIM scenario CO_2 emissions in year y. The Green and Red scenarios are used in section 4 to calculate the RED percentage.

In all the tables, the countries of interest (COI) are highlighted. The COI is composed of countries with global or regional influence, and includes Australia, Brazil, China, Canada, Germany, India, Japan, Russia, South Africa, the United States, and Switzerland.

B MGHG-CINT: Modified GHG Emission Cumulative Intensity

Although we are at the beginning of the global industrial boom of the 21st century, it can be argued that the cumulative emissions of countries should be considered rather than their current emission levels. This argument makes sense, as the GHG lifetimes in the atmosphere are usually long; for example, that of CH_4 is estimated to be a decade. To take this point into consideration, we have re-calculated all the variables in this section, to express them in cumulative form. The calculation period we selected is a decade, from 2000 to 2009. As the MGDP is a normalized figure, no conversion on the MGDP values has been applied. The GHG emissions and the Green and Red scenarios over the calculation period have been summed to obtain their cumulative versions. Table B.1 presents the top 5 countries and the COI countries in terms of their RED percentages. As can be concluded from the table, the difference between the annual (Table 7) and cumulative RED percentages is small, and so the annual values are sufficient, and perhaps more rewarding, for developing a short-term policy.

Rank	**Country**	**REDC %** ($\times 10^2$)
1	Turkmenistan	40.21
2	Zimbabwe	37.32
3	Congo, DRC	36.73
4	Zambia	31.16
